**A b s t r a c t.** In the present study soil-water coefficients  $k_{s1}$  were determined and evaluation of the influence of soil sucking pressure on the actual yield was carried out. Relations between these coefficients and soil sucking pressure in the root zone are used for the calculation of actual evapotranspiration or actual yield neglecting evaluation of the influence of evapotranspiration on yield.

**K e y w o r d s:** soil water, sucking pressure, evapotranspiration, meadow, yield.

### INTRODUCTION

Water is one of the most important factors that influences evapotranspiration and grass yield. When water appears in the soil in abundance, evapotranspiration and yields are maximum. In dry periods, soil moisture content measured by the level of sucking pressure, becomes a restricting factor for evapotranspiration and, hence grass yield. There is a close connection between yield and the amount of water for evapotranspiration [7]. The influence of soil sucking pressure on the actual evapotranspiration (pattern 1) and yield (pattern 2) can be determined by means of soil-water coefficients  $k_{s1}$  and  $k_{s2}$  that are related to the sucking pressure of soil water. The aim of the present study was to evaluate the influence of soil water sucking pressure  $F$  on the level of soil-water coefficients  $k_{s1}$  and  $k_{s2}$ .

### THEORETICAL BASIS

The influence of soil sucking pressure on the level of evapotranspiration can be determined from the soil-water coefficients  $k_s$  [4-6,9]. The above coefficients can be determined from the following equation:

$$ET - k_{s1}ET(Q_{\max}) \quad (1)$$

where:  $ET$  - seasonal values of actual evapotranspiration in the conditions of differentiated sucking pressure of soil water  $F_s$  [in mm];  $k_{s1}$  - soil-water coefficient related to the sucking pressure of soil water  $F$ ;  $ET(Q_{\max})$  - seasonal values of actual evapotranspiration at the maximum yield level without abundant water consumption (in mm).

Polish literature on the relations between soil-water coefficients  $k_s$  and soil sucking pressure is relatively poor [5,6,8,9]. The Eq.(1) enables calculation of soil coefficients  $k_{s1}$  for the first and second swath on the basis of  $ET$  and  $ET(Q_{\max})$  values and determination of relation between  $k_{s1}$  and sucking pressure  $F$  measured in lysimeters.

Plant growth consists in the transformation of radiation energy in the process of photosynthesis into plant biomass. In the conditions of water deficiency in the soil ( $k_s$  1.0), sucking pressure  $F$  decreases both the level of evapotranspiration  $ET$  and the yield level  $Q$ . If we assume identical reaction of both evapotranspiration and yield to water deficiency in the soil, then the influence of sucking pressure  $F$  on the actual yield level  $Q$  can be calculated from the following equation:

$$Q = k_{s2} Q_{\max} \quad (2)$$

where  $Q$  - actual yield level in the conditions of differentiated soil water sucking pressure  $F$ ;  $k_{s2}$  soil-water coefficients dependent on the soil water sucking pressure  $F$  and calculated in the aspect of direct influence of sucking pressure on yield;  $Q_{\max}$  - actual yield when  $k_{s2} = 1$  and  $Q = Q_{\max}$ .

For the evaluation of  $k_{s2}$  coefficients and their relation to the soil water sucking pressure  $F$ , it is indispensable to get to know the  $Q$ ,  $Q_{\max}$ , and  $F$  values. In the present work an attempt to determine the values of  $k_{s1}$  coefficients from the Eq.(1) and  $k_{s2}$  coefficients from the Eq.(2) in relation to the soil water sucking pressure  $F$  was undertaken.

## MATERIALS AND METHODS

The basis for the present work are the results of studies on the sucking pressure of peat-mucky soil, medium transformed soil utilised as 3-swath meadow together with yield and evapotranspiration of this meadow at differentiated depths of dewatering. The present studies were carried out in the region of Polesie Lubelskie in Sosnowica in the period 1977-1994. The values of sucking pressure and evapotranspiration taken every decade were then used for the determination of soil-water coefficients  $k_s$  in relation to sucking pressure  $F$  [9]. In the present study the

values of sucking pressure, evapotranspiration and yield were determined for individual swaths in the period 1977-1981 at the dewatering depths of 40, 50, 60, 70, and 90 cm; at the dewatering depths of 50, 60, 70, 90, and 100 cm in the period 1989-1994 and 70 and 100 cm in the period 1989-1994, as well as without ground water and covered lysimeters in the period from June to August.

To determine the relation between the  $k_{s1}$  and  $k_{s2}$  coefficients and soil water sucking pressure  $F$ , a GRAPHER software programme was used. Threshold values of the correlation coefficient  $r_\alpha$  and significance test  $F_\alpha$  as given by Elandt [1] were applied. They were related to the  $r$  and  $F$  values obtained from the calculations.

## RESULTS

Characteristics of actual evapotranspiration  $ET$  of a 3-swath highly fertilised meadow, yield  $Q$  and sucking pressure  $F$  at differentiated depths of dewatering  $h$  was limited to the mean daily values for the swaths in some chosen years, i.e., 1979, 1987, 1992 and for certain study periods (Table 1). Actual evapotranspiration  $Et$  at the maximum yield level  $Q_{\max}$ , i.e.,  $ET(Q_{\max})$  was assumed as an index of the highest water consumption by plants. Empirically determined values of  $ET(Q_{\max})$  and  $Q_{\max}$  are given in Table 1.

Dewatering depth  $h$  influenced the value of sucking pressure  $F$  (Table 1). Mean daily sucking pressure was the lowest at the dewatering depth of 40 cm and the highest in the lysimeters with broken capillary rise from the saturated zone (without ground water). The pressure in the second swath was slightly higher when compared to the third swath due to higher evapotranspiration (Table 1). Soil sucking pressure is a changing value that is related to the depth of dewatering and evapotranspiration level. The above agrees with the results of model [7] and field experiments [8].

### **Influence of soil water sucking pressure on the level of meadow evapotranspiration**

The influence of sucking pressure on the level of evapotranspiration is characterised by the values of  $k_{s1}$  coefficients calculated from the Eq.(1) and presented as examples for the years 1979, 1987, 1992 (Table 2) and relations between these coefficients and sucking pressure  $F$  in the second and third swath. The coefficients  $k_{s1}=1.00$  characterise dewatering depth at which actual yield  $Q=Q_{\max}$ ,  $ET=ET(Q_{\max})$  - Table 1. There is a supplement of water in the soil. The values of coefficients  $k_s < 1.00$  in individual swaths decrease when dewatering depth  $h$

**Table 1.** Daily means of actual evapotranspiration values ( $ET$ , mm d<sup>-1</sup>) for individual swaths, yields ( $Q$ , q ha<sup>-1</sup>d<sup>-1</sup>) and soil sucking pressure in the 0-30 cm layer ( $F$ , hPa) at differentiated depths of dewatering ( $h$ , cm) in some years and study periods in Sosnowica

| Dewatering depth, cm | Year, Study period   | $ET$ in swaths |             |             | $Q$ in swaths |             |             | $F$ in swaths |     |

**Table 2.** Differentiation of soil-water coefficients  $k_{s,f} = ET/ET_{max}$  for a 3-swath meadow on the Mtl bb in some years in relation to the dewatering depth ( $h$ , cm)

| Swath | Year | $K_{s,f} = Q/Q_{max}$ the dewatering level $h$ , cm |      |      |      |      | Without ground water |
|-------|------|---|------|------|------|------|----------------------|
|       |      | 50  | 60   | 70   | 90   | 100  |                      |
| I     | 1979 | 1.00  | 0.86 | 0.83 | 0.61 |      |                      |
|       | 1987 |   |      | 1.00 | 0.83 | 0.63 |                      |
|       | 1992 |   |      | 1.00 |      | 0.82 | 0.84                 |
| II    | 1979 |   | 1.00 | 0.83 | 0.73 |      |                      |
|       | 1987 | 1.00  | 0.78 | 0.81 | 0.57 | 0.47 |                      |
|       | 1992 |   |      | 1.00 |      | 0.59 | 0.35                 |
| III   | 1979 |   |      |      | 1.00 |      |                      |
|       | 1987 |   | 1.00 | 0.96 | 0.82 | 0.69 |                      |
|       | 1992 |   |      | 1.00 |      | 0.51 | 0.39                 |

increases. It results in a decrease of actual evapotranspiration  $ET$  due to the increase of sucking pressure  $F$  (Table 1).

The soil water coefficients  $k_{s1} \leq 1.00$  and the values of sucking pressure  $F$  related to them that were determined during study period, were then assumed as the basis for the calculation of  $k_{s1}(F)$  relations in the second and third swath. These relations for the second swath have the following form:

$$k_{s1} = 0.9919 - 0.0008F \quad (3)$$

where  $F$  - soil water sucking pressure in the root zone, in hPa.

It was obtained at the 44 degrees of freedom. This relation is characterised by the correlation coefficient  $r = 0.7708$  and the values of significance test  $F = 68.1$ . The threshold values of the correlation coefficient  $r_{\alpha} = 0.3725$  and significance test  $F_{\alpha} = 7.24$  are lower than the calculated ones. Hence, this relation is significant. It can be used for the evaluation of  $k_{s1}$  coefficients in the second swath on the basis of sucking pressure  $F$  in the range from 21 to 723 hPa and for the calculations of actual meadow evapotranspiration  $ET$  on the basis of  $ET(Q_{\max})$  that was  $4.1 \text{ mm d}^{-1}$  on the average (Table 1) and  $k_{s1}$  coefficients in the range of  $F$  values given above. The  $k_{s1}(F)$  relations for the third swath are as follows:

$$k_{s1} = 1.0206 - 0.0010 F \quad (4)$$

It was obtained at 32 degrees of freedom. This relation is characterised by: correlation coefficients  $r = 0.8248$  and  $r_{\alpha} = 0.4475$  and significance test  $F = 73.5$  and  $F_{\alpha} = 7.50$ . This relation can be useful in the evaluation of  $k_{s1}$  coefficients in the third swath on the basis of sucking pressure  $F$  in the range from 14 to 790 hPa. It can also be used for the evaluation of actual meadow evapotranspiration in the third swath on the basis of  $ET(Q_{\max})$  of  $1.8 \text{ mm d}^{-1}$  on the average (Table 1) and  $k_{s1}$  coefficients in the  $F$  range from 14 to 790 hPa.

The values of  $k_{s1}$  coefficients calculated on the basis of Eqs(3) and (4) at the sucking pressure  $F$  of 400 hPa are 0.65 and 0.62, respectively. They differ in their values, which confirms a significant influence of  $ET(Q_{\max})$  on the relation pattern  $k_{s1}(F)$  according to earlier studies by Feddes *et al.* [3].

### **Influence of soil water sucking pressure on the meadow yields**

The influence of sucking pressure  $F$  on the meadow yields are characterised by the values of  $k_{s2}$  coefficients calculated from the Eq.(2) and presented as examples for the years: 1979, 1987, 1992 (Table 3) and relations between  $k_{s2}$  coefficients

**Table 3.** Differentiated levels of soil-water coefficients  $k_{s2} - Q/Q_{max}$  for the 3-swath meadow in the Mt II bb soil in some years in relation to the depth of dewatering ( $h$ , cm)

| Swath | Year | $K_{s2} - Q/Q_{max}$ the dewatering level $h$ , cm |      |      |      |      | Without ground water |
|-------|------|--|------|------|------|------|----------------------|
|       |      | 50   | 60   | 70   | 90   | 100  |                      |
| I     | 1979 |  |      | 0.92 | 0.78 |      |                      |
|       | 1987 | 1.00   | 0.97 | 1.00 | 0.83 | 0.73 |                      |
|       | 1992 |  |      | 1.00 |      | 0.71 | 0.69                 |
| II    | 1979 |  | 1.00 | 0.92 | 0.80 |      |                      |
|       | 1987 | 1.00   | 0.92 | 0.80 | 0.41 | 0.48 |                      |
|       | 1992 |  |      | 1.00 |      | 0.67 | 0.32                 |
| III   | 1979 |  |      |      | 1.00 |      |                      |
|       | 1987 |  | 1.00 | 0.75 | 0.68 | 0.70 |                      |
|       | 1992 |  |      | 1.00 |      | 0.32 | 0.25                 |

and sucking pressure  $F$  in the second and third swath. The  $k_{s2}$  coefficients equal to 1.00 characterise such a dewatering depth  $h$  at which  $Q = Q_{max}$ . In the above conditions there is abundance of water in the soil. The  $k_{s2}$  values  $< 1.00$  in the individual swaths decrease when the depth of dewatering increases. It results from the restrictions of  $Q$  yields imposed by sucking pressure  $F$  (Table 1). The soil-water coefficients  $k_{s2} \leq 1.00$  and the values of sucking pressure  $F$  related to them that were determined during study period were then assumed as the basis for the calculation of  $k_{s2}(F)$  relations in the second and third swath. These relations for the second swath have the following form:

$$k_{s2} = 1.0007 - 0.0009F. \quad (5)$$

It was obtained at the 44 degrees of freedom. This relation is characterised by the correlation coefficients  $r=0.7501$  and  $r_{\alpha}=0.3725$  and the values of the significance test  $F=56.6$  and  $F_{\alpha}=7.24$ . This relation is then significant. It can be used for the evaluation of  $k_{s2}$  values on the basis of sucking pressure  $F$  in the range from 21 to 723 hPa and for the calculation of actual yields  $Q$  on the basis of maximum yields  $Q_{max}$  that are  $0.97 \text{ q ha}^{-1} \text{ d}^{-1}$  (Table 1) and the values of  $k_{s2}$  coefficients in the  $F$  range given above. This relation takes the following form for the third swath:

$$k_{s2} = 0.9673 - 0.0008F. \quad (6)$$

It was obtained at the 32 degrees of freedom. This relation is characterised by

the correlation coefficients  $r=0.6711$  and  $r_{\alpha}=0.4475$  and the values of significance tests of  $F=26.2$  and  $F_{\alpha}=7.50$ . Hence, this relation is significant. It can be applied for the evaluation of  $k_{s2}$  coefficients in the third swath on the basis of  $F$  sucking pressure in the range from 14 to 790 hPa and for the calculation of actual yields  $Q$  on the basis of  $Q-Q_{\max}$  that are  $0.50 \text{ q ha}^{-1} \text{ d}^{-1}$  (Table 1) and the values of  $k_{s2}$  coefficients in the  $F$  range given above.

The  $k_{s2}$  coefficients calculated from the Eqs(5) and (6) at the sucking pressure  $F=400$  hPa are the same and equal to 0.64. It means that the level of maximum yield is not a differentiating factor for the relation pattern  $k_{s2}(F)$ . The values of  $k_{s1}$  and  $k_{s2}$  coefficients calculated from the Eqs(3) and (5) at the sucking pressure  $F=400$  hPa are 0.65 and 0.64, respectively. The values of these coefficients as calculated simultaneously from the Eqs(4) and (6) are 0.62 and 0.64, respectively. It means that the influence of soil sucking pressure on the level of evapotranspiration and yield is only slightly different, which is basically in agreement with the studies by Łabędzki [6] and Feddes [2]. The hypothesis that yield is a function of actual evapotranspiration [7] is then confirmed.

## CONCLUSIONS

On the basis of analysis of the results obtained and calculations carried out, we can draw the following conclusions:

1. Soil-water coefficients  $k_{s1}=ET/ET(Q_{\max})$  and determined in this study and relations between these coefficients and soil sucking pressure in the second (Eq.(3)) and third (Eq.(4)) swath can be used for the evaluation of actual evapotranspiration of the meadow on the basis of evapotranspiration level at the maximum yield (Table 1) and  $k_{s1}$  coefficients in the sucking pressure range from 21 to 723 hPa and from 14 to 790 hPa, respectively.

2. The soil-water coefficients given in this study  $k_{s2} - Q/Q_{\max}$  and relations between these coefficients and soil sucking pressure in the second (Eq.(5)) and third (Eq.(6)) swath can be used for the evaluation of actual yields on the basis of maximum yield (Table 1) and  $k_{s2}$  coefficients in the sucking pressure ranges from 21 hPa to 723 hPa, and from 14 to 790 hPa, respectively.

3. The relations (3), (4), (5), and (6) presented in this study are relevant for the 2-swath meadow on the peat-mucky soil determined as Mt II bb. They can be used for the evaluation of the actual evapotranspiration level and yield value in the moist water logged habitat determined as Pb.
